Abstract
We study the link between the complexity of polynomial matrix multiplication and the complexity of solving other basic linear algebra problems on polynomial matrices. By polynomial matrices we mean \( n \times n \) matrices of degree \( d \) over \( K[x] \) where \( K \) is a commutative field. Under the straight-line program model we show that multiplication is reducible to the problem of computing the coefficient of degree \( d \) of the determinant. Conversely, we propose algorithms for minimal approximant computation and column reduction that are based on polynomial matrix multiplication; for the determinant, the straight-line program we give also relies on matrix product over \( K[x] \) and provides an alternative to the determinant algorithm of [16]. We further show that all these problems can be solved in particular in \( O(\tilde{n}^\omega d) \) operations in \( K \). Here the soft “O” notation indicates some missing \( \log(nd) \) factors and \( \omega \) is the exponent of matrix multiplication over \( K \).

Keywords: Matrix polynomial, minimal basis, column reduced form, matrix gcd, determinant, polynomial matrix multiplication.

Résumé
On étudie le lien entre la complexité du produit de matrices polynomiales et celle d’autres opérations élémentaires de l’algèbre linéaire des matrices polynomiales. Par matrices polynomiales on entend des matrices \( n \times n \) de degré \( d \) sur \( K[x] \), \( K \) étant un corps commutatif. Avec le modèle “straight-line” nous montrons que le produit se réduit au calcul du coefficient de degré \( d \) du déterminant. Réciproquement, on propose pour certains approximants matriciels minimaux et la forme colonne réduite des algorithmes basés sur le produit de matrices; pour le déterminant, on donne un programme “straight-line” également à base de produit matriciel, qui fournit une alternative à l’algorithme de [16]. On montre de plus que tous ces problèmes peuvent être résolus en particulier en \( O(\tilde{n}^\omega d) \) opérations sur \( K \). La notation \( O \) contient des facteurs \( \log(nd) \) et \( \omega \) est l’exposant du produit de matrices sur \( K \).

Mots-clés: Matrice polynomiale, base minimale, forme colonne réduite, pgcd matriciel, déterminant, produit de matrices polynomiales.
1 Introduction

The link between matrix multiplication and other basic linear algebra problems is well known under the algebraic complexity model. For $K$ a commutative field, we will assume that the product of two $n \times n$ matrices over $K$ can be computed in $O(n^\omega)$ operations in $K$. Under the model of computation trees over $K$, we know that $\omega$ is also the exponent of the problems of computing the determinant, the matrix inverse, the rank, the characteristic polynomial (we refer to the survey in [5, Chap.16]) or the Frobenius normal form [8, 15]. On an algebraic RAM, all these problems can be solved with $O'(n^\omega)$ operations in $K$, hence the corresponding algorithms are optimal up to logarithmic terms. Here and in the rest of the paper, for any exponent $e_1$, $O'(n^{e_1})$ denotes $O(n^{e_1 \log^2 n})$ for any exponent $e_2$.

Much less is known for polynomial matrices and even less for integer matrices under the bit-complexity model. Difficulties come from the size of the data (and from carry propagation in the case of integer arithmetic) which make reductions between problems hard to obtain. In this paper we investigate the case of matrices of degree $d$ in $K[x]^{n \times n}$. This is motivated both by the interest in studying more concrete domains than abstract fields and by the two results [16] and [10, 21]. Storjohann has established and algorithm of cost $O'(n^\omega d)$ for the determinant and the Smith normal form. We have shown that the matrix inverse can be computed by a straight-line program of length $O'(n^3 d)$ (which is almost the size of the output). Besides, the latter estimate gives an alternative for the determinant in $O'(n^\omega d)$ (see §4).

These two results first ask the following question: are problems on polynomial matrices – and especially the determinant problem – harder than polynomial matrix multiplication? By slightly extending the result of Baur & Strassen [1, Cor. 5] for matrices over a field, we answer positively for the determinant. We show in section 4 that if there is a straight-line program of length $D(n, d)$ over $K$ which computes the coefficient of degree $d$ of the determinant, then there is a straight-line program of length no more than $8D(n, d)$ which multiplies two $n \times n$ matrices of degree $d$.

Conversely, the second question is to know which polynomial matrix problems can be solved with roughly the same number of arithmetic operations than polynomial matrix multiplication. As seen above we already know that this is the case of the determinant problem [16] on an algebraic RAM using $O'(n^d)$ as an estimation of the complexity of matrix multiplication [6]. We will show in §4 that a different approach, which we have developed independently [10, 21], gives a straight-line program of length $O(n^d)$ for the same problem.

Before studying the determinant, we first give analogous cost estimates with RAM programs for two other problems: we show in section 2 how to compute minimal bases and order $d$ matrix approximants in $O'(n^d)$ operations in $K$; we show in section 3 that an invertible matrix can be column reduced in time $O'(n^d)$ as well. Note that here column reduction is roughly lattice basis reduction for $K[x]$-modules.

We further study the complexities of each of the above problems in terms of general cost functions involving polynomial matrix multiplication. To do so, we denote by $MM(n, d)$ the cost of multiplying two matrices of degree $d$ in $K[x]^{n \times n}$ (with $MM(n) = MM(n, 0)$) and assume without loss of generality that $n$ and $d$ are powers of two. As we shall see in section 2.2 our minimal basis algorithm works recursively on the degree and leads us to define the function

$$MM'(n, d) = \sum_{i=0}^{\log d} 2^i MM(n, 2^{-i}d).$$

This will be used in sections 2 and 3 for expressing the costs of matrix approximation and column reduction. In the same way, the determinant algorithms of section 4 work recursively on the
dimension and we give their complexities in terms of the function

\[ \text{MM}''(n, d) = \sum_{i=0}^{\log n} 2^i \text{MM}(2^{-i}n, 2^i d). \]

For \( \text{MM}(n, d) = \Theta(n^{\omega} d \log d \log \log d) \) [6] these two functions further simplify. We have \( \text{MM}'(n, d) = O(\text{MM}(n, d) \log d) \) for any value of \( \omega \) and \( \text{MM}''(n, d) = O(\text{MM}(n, d) \log n) \) if \( \omega = 2 \) and \( \text{MM}''(n, d) = O(\text{MM}(n, d)) \) if \( \omega > 2 \). Therefore

\[ \text{MM}'(m, d) = O(\text{MM}(n, d) \log d), \quad \text{MM}''(m, d) = O(\text{MM}(n, d)) \]

when taking \( \text{MM}(n, d) = \Theta(n^{\omega} d) \).

## 2 Minimal basis computation

Many problems on matrix polynomials reduce to computing minimal approximant bases (or \( \sigma \)-bases) [2]. Given a matrix power series \( G \in K[[x]]^{m \times n} \) and an approximation order \( d \in \mathbb{N} \), these bases are nonsingular \( m \times m \) polynomial matrices \( M \) such that

\[ MG = O(x^d). \quad (1) \]

Minimality is made precise in Definition 2.1 below. It essentially expresses the fact that \( M \) has the smallest possible row degrees.

Minimal basis computations are motivated by the following two applications, which we shall develop later in the paper: in section 3 we will use the fact that the problem of column reducing a matrix can be solved by computing a Padé approximant and thus a minimal approximant basis; in section 4 we further use such approximants for recovering the polynomial matrix kernels that lead to the determinant. Note that a third application is the computation of minimal matrix polynomials of linearly generated matrix sequences as proposed in [23] and [20].

Our purpose in this section is to introduce polynomial matrix multiplication into the existing approximation algorithms. We achieve this by first adapting in §2.1 the \( \sigma \)-basis algorithm of Beckermann and Labahn [2] to exploit fast matrix multiplication over \( K \). Roughly, the algorithm of [2] works iteratively and computes a \( \sigma \)-basis from a \( (\sigma - n) \)-basis via \( n \) Gaussian elimination steps on vectors of \( K^m \). How to replace these \( n \) steps on \( m \times 1 \) vectors with a single step on an \( m \times n \) matrix was unclear. We solve this problem by resorting to the blocking approach of Coppersmith [7, 13] and using the matrix product-based LSP factorization algorithm of [9]. Polynomial matrix product then arises in §2.2 with a divide-and-conquer version of the method of §2.1 that generalizes the previous studies in [2, 19].

This divide-and-conquer version yields the cost of \( O(n^{\omega} d) \) which improves upon the cost of \( O(n^3 d) \) in [2, Theorem 6.2].

To define the type of approximants we compute, we consider as in [2] the formal power series vector

\[ f(x) = G(x^n)[1, x, \ldots, x^{n-1}]^T \in K[[x]]^m; \]

we further call (approximation) order of \( v^T \in K[x]^m \) and denote by \( \text{ord} v \) the integer

\[ \text{ord} v = \sup\{ \tau \in \mathbb{N} : v(x^\tau) f(x) = O(x^\tau) \}. \]

For \( \sigma \in \mathbb{N} \) we then define \( \sigma \)-bases with respect to the rows of \( G \) as follows.
Definition 2.1 A \( \sigma \)-basis of \( G \) is a matrix polynomial \( M \) in \( K[x]^{m \times m} \) verifying:

1) \( \text{ord} M^{(i, \ast)} \geq \sigma \) for \( 1 \leq i \leq m \);

ii) every \( v \in K[x]^m \) such that \( \text{ord} v \geq \sigma \) admits a unique decomposition \( v^T = \sum_{i=1}^{m} c^{(i)} M^{(i, \ast)} \) where, for \( 1 \leq i \leq m \), \( c^{(i)} \in K[x] \) and \( \text{deg} c^{(i)} + \text{deg} M^{(i, \ast)} \leq \text{deg} v \) (minimality of the approximant).

This definition coincides with [2, Definition 3.2, p.809] when the \( m \) components of the multiindex in [2] are the same. Also, since i) yields \( M(x^n)G(x^n) [1, x, \ldots, x^{n-1}]^T = O(x^\sigma) \), it suffices to take \( \sigma = nd \) to get approximant \( M(x) \) in (1).

2.1 Via matrix multiplication

To introduce matrix multiplication into \( \sigma \)-basis computations of [2], we use the so-called LSP factorization [3, p. 103]: every matrix \( A \in K^{m \times m} \) of rank \( r \) can be written as \( A = LSP \) where \( L \in K^{m \times m} \) is lower triangular with ones on the diagonal, \( S \in K^{m \times m} \) has \( m - r \) zero rows and \( P \in K^{m \times m} \) is a permutation matrix; additionally, the nonzero rows of \( S \) form an \( r \times m \) upper triangular matrix with nonzero diagonal entries. Let

\[
1 \leq i_1 < i_2 < \cdots < i_r \leq m
\]

be the indices of the nonzero rows of \( S \). Each \( i_j \) is then uniquely defined as the smallest index such that the first \( i_j \) rows of \( A \) have rank \( j \).

In Algorithm \textbf{SigmaBasis} below, we assume we compute LSP factorizations with the algorithm of [9] as described in [3, p. 103]: \( L, S, P \) are computed in \( O(MM(m)) \) operations in \( K \); furthermore, \( L, S \) are such that if the \( i \)th row of \( S \) is identically zero then the \( i \)th column of \( L \) is the \( i \)th unit vector. (See Appendix A.)

\textbf{Algorithm SigmaBasis}(\( G, d \))
\textbf{Input}: \( G \in K[[x]]^{m \times n} \) with \( m \geq n \) and \( d \in \mathbb{N} \).
\textbf{Output}: a \( \sigma \)-basis \( M \in K[x]^{m \times m} \) with \( \sigma = nd \).

\[
\begin{align*}
M &:= I_m; \\
\delta &:= 0 \in \mathbb{N}^m; \\
\text{for} \ k \text{ from 1 to } d \text{ do} & \\
\delta &:= \pi \delta \text{ where } \pi \in K^{m \times m} \text{ sorts } \delta \text{ in decreasing order}; \\
\Delta &:= x^{-(k-1)} \pi MG \mod x; \\
\Delta &:= \Delta \text{ augmented with } m - n \text{ zero columns}; \\
\text{Compute the LSP factorization of } \Delta; \\
D &:= \text{diag}(d_1, \ldots, d_m) \text{ where } d_i = x \text{ if } i \in \{ i_1, \ldots, i_r \} \\
\text{ and } d_i = 1 \text{ otherwise}; \\
M &:= DL^{-1} \pi M; \\
\delta &:= \delta + |d_1(0) - 1, \ldots, d_m(0) - 1| \od; \\
\text{return } M;
\end{align*}
\]

\textbf{Lemma 2.2} Algorithm \textbf{BlockSigmaBasis} is correct. Its cost is \( O(MM(m) d^2) \) or \( O(n^2 d^2) \) operations in \( K \).

\textbf{Proof}. Let \( M_0 = I_m \) and, for \( 1 \leq k \leq d \), write \( M_k(x) \) for the matrix \( M \) computed by step \( k \). We see that the degree of \( M_k \) in \( x \) is no more than \( k \) and, assuming the algorithm is correct,
that $M_k G = O(x^k)$. The computation of $\Delta$ at step $k$ thus costs $O(\text{MM}(m)k)$ field operations. This dominates the cost of step $k$, for both LSP factorization and the update of $M$ require only $O(\text{MM}(m))$ operations in $K$. The overall complexity then follows.

To prove the algorithm is correct, note first that $M_0$ is a 0-basis of $G(x)$. Then, assuming for $k \in \{1, \ldots, m\}$ that $M_{k-1}(x)$ is an $(nk-1)$-basis of $G(x)$, we verify that $M_k(x) = D(x)L^{-1}\pi M_{k-1}(x)$ is an $nk$-basis of $G(x)$.

Let $N_{k-1}(x) = \pi M_{k-1}(x)$ and recall that $P$ is the permutation matrix in the LSP factorization at step $k$. It follows that $N_k(x)$ is an $(nk-1)$-basis of $G(x)^{P^{-1}}$. Algorithm FPSPS of [2, p. 810] with input parameters $m$, $n$,

$$F(x) = N_{k-1}(x^n)G(x^n)P^{-1}[1, x, \ldots, x^{n-1}]^T$$

and $(0, \ldots, 0) \in \mathbb{N}^m$ then returns an $nk$-basis of $G(x)^{P^{-1}}$ after $n$ steps. We denote this basis by $N_k(x)$. (Uniqueness of the output of FPSPS is explained in [2, p. 818].) As shown below, the two bases are related as

$$N_k(x) = D(x)L^{-1}N_{k-1}(x) \quad (2)$$

and hence $M_k = N_k$ is an $nk$-basis of $GP^{-1}$ and $G$ as well.

We now prove identity (2). Let $\Lambda = \Delta P^{-1}$ and let $\Lambda_j$ be the $j$th column of $\Lambda$. Then

$$x^{-(k-1)n}F(x) \equiv \Lambda_1 + x\Lambda_2 + \cdots + x^{n-1}\Lambda_n \mod x^n.$$

Since the rows of $N_{k-1}$ have been sorted by permutation $\pi$, the first step of FPSPS simply consists in picking the first nonzero entry of $\Lambda_1$ − say, $\lambda_1$ with row index $h_1$ − and zeroing the lower entries of $\Lambda_1$ by using pivot $\lambda_1$. The $h_1$st row is then multiplied by $x$. In other words, $N_{k-1}(x)$ is transformed into $E_1(x)T_1N_{k-1}(x)$ where we define $E_1(x) = \text{diag}(I_{h_1-1}, x, I_{m-h_1})$ and

$$T_1 = \begin{bmatrix} I_{h_1-1} & 1 \\ t_1 & I_{m-h_1} \end{bmatrix} \text{ with } t_1 \in K^{m-h_1}. \quad (3)$$

Recalling that $i_1$ is the index of the first nonzero row of $S$ in factorization $\Lambda = LS$, we verify first that $h_1 = i_1$: it follows from Appendix A that $L$ and $S$ can be partitioned as

$$\Lambda = LS = \begin{bmatrix} I_{i_1-1} & 1 \\ t_1 & L' \end{bmatrix} \begin{bmatrix} \lambda_1 & s_i \\ S_l & S' \end{bmatrix}, \quad \lambda_1 \in K \setminus \{0\}.$$

Here $L' \in K^{(m-i_1) \times (m-i_1)}$, $S' \in K^{(m-i_1) \times (n-1)}$ and $\lambda_1$ is indeed the first nonzero entry of $\Lambda_1$. Hence $h_1 = i_1$. Second, comparing the first column in both members of $T_1\Lambda = T_1LS$ yields $t_1 = -l_1$ and the $i_1$st column of $T_1^{-1}$ is thus equal to the $i_1$st column of $L$. The first step of FPSPS yields eventually

$$x^{-(k-1)n}E_1(x^n)T_1F(x) \equiv x\lambda'_2 + \cdots + x^{n-1}\lambda'_n \mod x^n$$

where

$$[0|\lambda'_2| \cdots |\lambda'_n] = E_1(0)T_1\Lambda = \begin{bmatrix} 0 \\ 0 \\ L'S' \end{bmatrix} \in K^{m \times n}. \quad (4)$$

Let $h_2$ be the pivot index at step 2 and let $T_2$ and $E_2(x)$ be the associated transformation matrices. It follows from (4) that $h_2 > i_1$. Hence $T_2$ has the form $T_2 = \text{diag}(I_{i_1}, T_2')$ and $E_1(x)$ commutes with $T_2$. Then, noticing that the ordering imposed by $\pi$ is still the same, one can iterate by replacing $T_1$, $LS$ and $i_1 < \cdots < i_r$ with respectively $T_2$, $L'S'$ and $i_2 - i_1 < \cdots < i_r - i_1$. We
eventually get $h_j = i_j$ for $1 \leq j \leq r$. Therefore, defining for $1 \leq j \leq r$ matrices $E_j(x)$ and $T_j$ has done in (3) for $j = 1$, we have

$$N_k(x) = E_r(x) \cdots E_2(x)E_1(x)T_r \cdots T_2T_1N_{k-1}(x).$$  \hfill (5)

It follows that $E_r(x) \cdots E_2(x)E_1(x) = D(x)$ and that the $i_j$th column of $T_j^{-1}$ equals the $i_j$th column of $L$. Noticing further that because of the structure of $T_j$ the $i_j$th column of $T_j^{-1}$ equals the $i_j$th column of $T_j^{-1}$, we have $T^{-1} = L$ and (2) follows from (5). \hfill \Box

2.2 Via polynomial matrix multiplication

To use polynomial matrix multiplication, we now give a divide-and-conquer version of Algorithm SigmaBasis. This version is based on the following “transitivity lemma”, which may be seen as the counterpart of Theorem 6.1 in [2] and can be shown in the same way.

**Lemma 2.3** If $M, M', M''$ are the output of Algorithm SigmaBasis for input $(G, d), (G, d/2), (x^{-d/2}M'G, d/2)$ respectively then $M = M''M'$.

**Algorithm BlockSigmaBasis**

**Input:** $G \in K[[x]]^{m \times n}$ with $m \geq n$ and $d \in \mathbb{N}$.

**Output:** a $\sigma$-basis $M \in K[x]^{m \times m}$ with $\sigma = nd$.

**Condition:** $d = 0$ or $\log d \in \mathbb{N}$.

if $d = 0$ then $M := I_m$;
else if $d = 1$ then $M := \text{SigmaBasis}(G, d)$;
else if $d \geq 2$ then
    $M' := \text{BlockSigmaBasis}(G, d/2)$;
    $M'' := \text{BlockSigmaBasis}(x^{-d/2}M'G \mod x^{d/2}, d/2)$;
    $M := M''M'$;
fi;
return $M$;

**Theorem 2.4** Algorithm BlockSigmaBasis is correct. Its cost is $1.5MM'(m, d) + O(dMM(m))$ or $O(mn^2d)$ operations in $K$.

**Proof.** For correctness it suffices to show that the algorithm with input $(G, d)$ uses only the first $d$ coefficients of series $G$: when $d = 1$ this is true because of Algorithm SigmaBasis; if we assume this is true for a given $d/2$ then this is still true for $d$ since $x^{-d/2}M'G \mod x^{d/2}$ depends only on $G \mod x^d$. Correctness then follows immediately from Lemma 2.3.

Now about complexity. First, it follows from Algorithm SigmaBasis that $\deg M \leq d$. Hence the product $M''M'$ costs $MM(m, d/2)$. Second, since $\deg M' \leq d/2$, the coefficient in $x^i$ of $x^{-d/2}M'G \mod x^{d/2}$ is the coefficient in $x^{i+d/2}$ of $M'(G \mod x^d)$. This product costs $MM(m, d)$. The cost $C(m, n, d)$ of Algorithm BlockSigmaBasis thus satisfies $C(m, n, 1) = O(MM(m))$ and, for $d \geq 2$,

$$C(m, n, d) \leq 2C(m, n, d/2) + MM(m, d/2) + MM(m, d).$$

This gives the bound $1.5MM'(m, d) + O(dMM(m))$.
3 Column reduction

For $A \in K[x]^{n \times n}$ we consider the problem of computing $C \in K[x]^{n \times n}$ such that $C = AU$ is column reduced, $U$ being a unimodular matrix over $K[x]$. Column reduction is essentially lattice basis reduction for $K[x]$-modules. To define the reduction, let $d_j$ denote the degree of the $j$th column of $C$. The corresponding coefficient vector of $x^{d_j}$ is the $j$th leading vector of $C$. We let $[C]_l$ be the matrix of these leading vectors.

**Definition 3.1** A matrix $C$ is column reduced if its leading coefficient matrix satisfies $\text{rank } [C]_l = \text{rank } C$.

We refer to [14, 22] and the references therein for discussions on previous reduction algorithms and applications of the form especially in linear algebra and in linear control theory. If $r$ is the rank of $A$, the best previously known cost for reducing $A$ was $O(n^2r^2)$ operations in $K$ [14]. Thus in particular $O(n^3d^2)$ for a nonsingular matrix. Here we propose a different approach which takes advantage of fast polynomial matrix multiplication and gives in particular the complexity estimate $O(\tilde{n}^\omega d)$.

We assume that $A$ of degree $d$ is nonsingular in $K[x]^{n \times n}$. The general case would require further developments. We compute a column reduced form of $A$ by combining our techniques in [22] to the high-order lifting and the integrality certificate in [16, §9]. The main idea is to reduce the problem to the computation of a matrix Padé approximant whose side-effect is to normalize the involved matrices [22]. Let us first recall the definition of right matrix greatest common divisors.

**Definition 3.2** A right matrix gcd of $P \in K[x]^{m \times n}$ and $A \in K[x]^{n \times n}$ is any full row rank matrix $G$ such that $U[P A] = \begin{bmatrix} G \\ 0 \end{bmatrix}$ with $U$ unimodular.

Right gcd’s are not unique, but if $[P^T A^T]^T$ has full column rank —here this is true by assumption— then, for given matrices $P$ and $A$, all the gcd’s are nonsingular and left equivalent (up to multiplication by a unimodular matrix on the left) in $K[x]^{n \times n}$. This also leads to the notion of an irreducible matrix fraction description. (See for example [11] for a detailed study of matrix gcd’s and fractions.)

**Definition 3.3** If a right gcd of $P$ and $A$ is unimodular then we say that $P$ and $A$ are relatively prime and that $PA^{-1}$ is an irreducible right matrix fraction description.

The whole algorithm for column reduction will be given in §3.3. The first step, detailed in §3.1, is to compute from $A$ a strictly proper and irreducible right fraction description

$$H = RA^{-1} \in K(x)^{n \times n}, \quad R \in K[x]^{n \times n}. \quad (6)$$

We recall that strictly proper means that $H$ tends to zero when $x$ tends to infinity. This implies that the degree of the $j$th column of $R$ must be strictly lower than the degree of the $j$th column of $A$. Since the degrees of $R$ and $A$ are bounded by $d$, the second step of the method, studied in §3.2, is to compute from the first $2d + 1$ terms of the expansion of $H$ a right matrix Padé approximant $H = TC^{-1}$ of $H$. Such an approximant, obtained from the results of §2 and [2], will have the additional property that $C$ is column reduced. We will see that by the equivalence of irreducible fractions, $C$ will be a column reduced form of $A$. 

6
Like the algorithms in [16], our column reduction algorithm is randomized Las Vegas since the first step requires that det $A(0) \neq 0$. Without loss of generality this may be assumed by choosing a random element $x_0$ in $K$ and by computing a column reduced form $C$ of $A(x + x_0)$. Indeed, a column reduced form of $A$ is then recovered as $C(x - x_0)$.

### 3.1 A strictly proper and irreducible fraction

For a given $A$, its inverse $A^{-1}$ may not be a strictly proper rational function, a case where $R = I$ is not a suitable choice in (6). We show that the integrality certificate of [16, §9] can be used here to find a target strictly proper function.

**Lemma 3.4** Let $A \in K[x]^{n \times n}$ of degree $d$ be such that $\det A(0) \neq 0$. For $h > (n - 1)d$ define $R \in K[x]^{n \times n}$ by

$$I = (A^{-1} \mod x^h) A + x^h R.$$  

(7)

The fraction $RA^{-1}$ is strictly proper and irreducible. If $h$ is the closest power of 2 greater than $(n - 1)d + 1$, the $2d + 1$ first terms of the expansion of $RA^{-1}$ may be computed at the cost of $O(MM(n, d) \log n) + O(n^2d)$ operations in $K$.

**Proof.** Identity (7) is identity (12) in [16] with $B = I$ and $T = A$. This is a Euclidean matrix division with coefficients in reverse order. The fraction $RA^{-1}$ is strictly proper because

$$RA^{-1} = x^{-h} A^{-1} - x^{-h} (A^{-1} \mod x^h)$$  

(8)

and $h > (n - 1)d \geq \deg A^*$ where $A^*$ is the adjoint matrix of $A$. On the other hand, there is a unimodular $U$ such that

$$[ x^h R A ] = [ I \ 0 ] -(A^{-1} \mod x^h) [ I \ A ] = U \begin{bmatrix} I & 0 \end{bmatrix}.$$  

Hence matrices $x^h R$ and $A$ are relatively prime (see Definition 3.2) and the same is true for $R$ and $A$.

For $h$ as in the statement, the $2d + 1$ terms of the expansion of $RA^{-1}$ may be computed by high-order $x^d$-lifting [16, §8] with input parameters $A$, $I$, $h$ and $2d + 1$. The corresponding cost in [16, Proposition 13] is $O(n^2d)$. It can be seen from [16] that the algorithm actually runs at a cost of $O(MM(n, d) \log n) + O(n^2 d)$ operations in $K$.  

### 3.2 Padé approximation and reduction

The key observation is that the descriptions $TC^{-1}$ of $H$ with $C$ a column reduced form of $A$ are those whose numerator and denominator matrices have minimal degrees (see Corollary 3.6 below). By definition they satisfy

$$\begin{bmatrix} H & -I \end{bmatrix} \begin{bmatrix} C \\ T \end{bmatrix} = 0 \mod x^{2d+1}$$

and, as we shall see, their minimality implies that they must appear in any $\sigma$-basis of $G = [H - I]$ for $\sigma = n(2d + 1)$. (Here we consider $\sigma$-bases with respect to the columns rather than the rows. Hence we transpose the matrices of section 2.)

To describe the set of all matrices $T$ and $C$ we use the notion of minimal basis of a module. For $M \in K[x]^{n \times m}$, $m > n$, with rank $n$, let $N \in K[x]^{m \times (m-n)}$ with columns forming a basis of the $K[x]$-submodule $\ker M$. We denote by $d_1, d_2, \ldots, d_{m-n}$ the column degrees of $N$ and assume they are ordered as $d_1 \leq d_2 \leq \cdots \leq d_{m-n}$. Then we have the following theorem and consequence.
Theorem 3.5 [11, §6.5.4]. If $N$ is column reduced then the column degrees $d'_1 \leq d'_2 \leq \cdots \leq d'_{m-n}$ of any other basis of ker $M$ satisfy $d'_j \geq d_j$ for $1 \leq j \leq m-n$. We say that the columns of $N$ form a minimal basis of ker $M$.

Corollary 3.6 A basis $[CT \ T]^T$ of ker $G = \ker[H - I]$ is minimal if and only if $C$ is a column reduced form of $A$.

Proof. If $[CT \ T]^T$ is a minimal basis then $H = TC^{-1}$ must be irreducible, otherwise the simplification of $(T, C)$ by a right matrix gcd would lead to a basis with smaller degrees. The latter would contradict Theorem 3.5. In addition since $[CT \ T]^T$ is column reduced then $C$ is column reduced. Indeed, $H$ being strictly proper implies that $T$ has column degrees strictly lower than those of $C$ which thus dominate. By [11, Theorem 6.5-4] we further know that two irreducible descriptions $TC^{-1}$ and $RA^{-1}$ of the same function $H$ have equivalent denominators. This means that there exists a unimodular $U$ such that $C = AU$. Hence $C$ is a column reduced form of $A$. Conversely, if $C$ in a basis $[CT \ T]^T$ is a column reduced form of $A$ then by Theorem 6.5-4 cited above, $TC^{-1}$ is an irreducible description of $H$. Since $C$ is column reduced, the non-minimality of $[CT \ T]^T$ as a basis of ker $G$ would then contradict its irreducibility. □

We now show that, for $\sigma$ large enough, a $\sigma$-basis with respect to the columns of $[H - I]$ leads to a minimal basis $[CT \ T]^T$ as in the corollary, and hence to a column reduced form of $A$. We follow here the techniques in [10] for computing a minimal basis of the kernel of a polynomial matrix.

Lemma 3.7 Let $N \in K[x]^{2n \times 2n}$ be a $\sigma$-basis with respect to the columns of $G = [H - I]$. If $\sigma \geq n(2d + 1)$, then the $n$ columns of $N$ of degree at most $d$ define an irreducible description $TC^{-1}$ of $H$ with $C$ a column reduced form of $A$.

Proof. We first show that there may be at most one set of $n$ columns of $N$ of degree at most $d$. Then the minimality of the $\sigma$-basis will imply its existence and the fact that it leads to a fraction description of the form $TC^{-1}$.

If $[Q^T \ P]^T$ is a set of $n$ columns of $N$ of degrees bounded by $d$ then

$$HQ - P \equiv 0 \mod x^{2d+1}.$$ 

If $A^{-1}S$ is a left description of $H$, defined in the same way as $RA^{-1}$ in Lemma 3.4, we get

$$SQ - AP \equiv 0 \mod x^{2d+1}.$$ 

Since every matrix in the latter identity has degree at most $d$ we deduce that

$$SQ - AP = 0.$$ (9)

It follows from the columns of a $\sigma$-basis $N$ being linearly independent over $K(x)$ [2] that $[Q^T \ P]^T$ has full column rank. Since (9) implies that

$$\begin{bmatrix} 1 & 0 \\ S & -A \end{bmatrix} \begin{bmatrix} Q \\ P \end{bmatrix} = \begin{bmatrix} Q \\ 0 \end{bmatrix},$$

we see that $Q$ is invertible and satisfies

$$PQ^{-1} = A^{-1}S = H.$$ (10)

Another choice $[Q^T \ P]^T$ of $n$ such columns would give $H = PQ^{-1} = P_1Q_1^{-1}$. By [11, Theorem 6.5-4] the two descriptions would verify

$$\begin{bmatrix} Q \\ P \end{bmatrix} P_2 = \begin{bmatrix} Q_1 \\ P_1 \end{bmatrix}.$$
and this would contradict the nonsingularity of the $\sigma$-basis. Hence the choice $[Q^T \ P^T]^T$ must be unique as announced.

Let $d_1, \ldots, d_n$ be the minimal degrees given by the columns of a minimal description $[C^T \ T^T]^T$ and let $v_1, \ldots, v_n$ be the corresponding columns. From ii) in Definition 2.1, $v_1$ can be written as

$$v_1 = \sum_{j=1}^{2n} c_{i_1}^{(j)} N_j, \text{ with } \deg c_{i_1}^{(j)} + \deg N_j \leq d_1$$

where $N_j$ is the $j$th column of the $\sigma$-basis $N$. Thus one column of $N$ has degree bounded by $d_1$. Now assume that $N$ has $k-1$ columns of degrees $d_1, \ldots, d_{k-1}$ with $v_k$ not belonging to the corresponding submodule. As for $k = 1$, there exists a column of $N$, linearly independent with respect to the first $k-1$ chosen ones, of degree bounded by $d_k$. Therefore $N$ contains $n$ distinct columns of degrees bounded by $d_1, \ldots, d_n$ and, by (10), in the kernel of $[H - I]$. Lemma 3.7 shows in conclusion that these $n$ columns give $C$, a column reduced form of $A$, in their first $n$ rows. □

We may notice that the result of the lemma would be true as soon as $\sigma > 2nd$ for the computation of an approximant of type $(d-1, d)$ as defined in [2].

### 3.3 Cost of the reduction

Our column reduction algorithm can be stated as follows.

**Algorithm** ColumnReduction($A$)

**Input:** $A \in K[x]^{n \times n}$ of degree $d$.

**Output:** $C = AU$ a column reduced form of $A$.

**Condition:** $A$ is nonsingular.

Choice of a random $x_0$ in $K$;

if $\det A(x_0) = 0$ then fail; /* $A$ is probably singular*/

$B := A(x + x_0)$;

$h := (n - 1)d + 1$;

$H := (B^{h-1} - (B^{h-1} \mod x^h))/x^h \mod x^{2d+1}$;

$TC^{-1} :=$ a Padé approximant of $H \mod x^{2d+1}$;

return $C(x - x_0)$;

Its complexity follows from Lemma 3.4 concerning the computation of the first terms of $H$, and from Theorem 2.4 concerning the computation of the $n(2d + 1)$-basis of Lemma 3.7.

**Theorem 3.8** A column reduced form of a nonsingular matrix $A$ of degree $d$ in $K[x]^{n \times n}$ can be computed by a Las Vegas (certified) algorithm in $O(MM'(n,d) + MM(n,d) \log n) + O^{\tilde{\eta}}(n^d)$ operations in $K$.

### 4 Matrix product & determinant

The link between matrix multiplication and determinant computation over a field $K$ is well known. We may refer to [5, Chap.16] for a survey of the question. If we have an algorithm for multiplying two matrices with $MM(n)$ operations in $K$ then we have an algorithm (algebraic RAM) for computing the determinant with $O(MM(n))$ operations in $K$ [4]. Conversely, the exponents (computation tree) of matrix multiplication and of determinant computation coincide [18, 1]. Furthermore, if we have a randomized Monte Carlo algorithm which computes the determinant
with $D(n)$ operations in $K$ then we have a Monte Carlo algorithm for multiplying two matrices with $O(D(n))$ operations in $K$ [8, Theorem 1.3].

In this section we show that similar results hold for polynomial matrices of degree $d$. In §4.1, using a slight extension of Baur & Strassen’s idea [1, Cor. 5], we propose a reduction of polynomial matrix multiplication to determinant computation. Then in §4.2, based on the techniques in [16, 21, 10], we investigate the reverse reduction.

We use two models of computation, algebraic straight-line programs or algorithms on an algebraic RAM.

### 4.1 Polynomial matrix multiplication

Baur & Strassen [1, Cor. 5] in conjunction with [18, 4] have shown that a straight-line program of length $D(n)$ for computing the determinant of a matrix $A$ in $K^{n \times n}$ can be transformed into a program of length bounded by $O(D(n))$ for matrix multiplication. Indeed, the problem of multiplying two matrices can be reduced to matrix inversion [18, 4]. Then matrix inversion is reduced to the problem of computing the determinant by differentiation of the program of length $D(n)$ [12, 1].

The complexity estimate $O(D(n))$ for matrix multiplication relies on the computation of the partial derivatives of the determinant as a function in $K[a_{1,1}, \ldots, a_{i,j}, \ldots, a_{n,n}]$. The $a_{i,j}$'s are indeterminates standing for the entries of the input matrix. It was not clear how to extend the result to polynomial matrices. The output of a program of length $D(n, d)$ over $K$ which computes the determinant of a polynomial matrix is a function in $K[x, a_{1,1}, \ldots, a_{i,j}, \ldots, a_{n,n}]$, that is, a set of functions in $K[a_{1,1}, \ldots, a_{i,j}, \ldots, a_{n,n}]$. A straightforward idea could be to differentiate at least $d$ such functions, but it is not known how to do it without increasing the complexity estimate $O(D(n, d))$.

Here we remark that having only one particular coefficient of the polynomial matrix determinant is sufficient for recovering the first $d + 1$ coefficients of the polynomial entries of the adjoint matrix $A^* = (\det A)^{-1} A^{-1} \in K[x]^{n \times n}$. Hence we first compute $A^*$ modulo $x^{d+1}$ and from there, the multiplication of two matrices of degree $d$ is easily deduced.

Let $A \in K[x]^{n \times n}$ have degree $d$ and denote its $(i,j)$ entry by $a_{i,j} = \sum_{k=0}^{d} a_{i,j,k} x^k$. Let further $a_{i,j}^* = \sum_{k=0}^{d} a_{i,j,k}^* x^k$ be the $(i,j)$ entry of the adjoint matrix $A^*$ of $A$ and let $\Delta = \sum_{l=0}^{d} \Delta_l x^l$ be the determinant of $A$. We have the following relation between the partial derivatives of coefficient $\Delta_l$ and some of the $a_{i,j,k}^*$'s.

**Lemma 4.1** The partial derivatives of the coefficients of the determinant and the coefficients of the adjoint matrix satisfy

$$a_{j,i,l-k}^* = \frac{\partial \Delta_l}{\partial a_{i,j,k}}, \quad 0 \leq l \leq nd, \quad 0 \leq k \leq d.$$

where, by convention, $a_{j,i,k}^* = 0$ if $k < 0$ or $k > nd - d$.

**Proof.** By Cramer’s rule and since $\partial a_{i,j}/\partial a_{i,j,k} = x^k$, we have $\partial \Delta/\partial a_{i,j,k} = x^k a_{i,j}^*$. On the other hand, for $1 \leq k \leq d$ the coefficients $\Delta_0, \ldots, \Delta_{k-1}$ do not depend on variable $a_{i,j,k}$ and thus $\partial \Delta/\partial a_{i,j,k} = \sum_{l=k}^{nd} \partial \Delta_l/\partial a_{i,j,k} x^l$. Therefore

$$\sum_{l=0}^{nd-d} a_{j,i,l} x^{k+l} = \sum_{l=0}^{nd-k} \frac{\partial \Delta_{k+l}}{\partial a_{i,j,k}} x^{k+l}$$

and the result follows by identifying the coefficients. \qed
Theorem 4.2 If there is a straight-line program of length \( O(n^d) \) over \( K \) which computes the \((d+1)\)st coefficient of the determinant of an \( n \times n \) matrix of degree \( d \), then there is a straight-line program of length no more than \( 8D(n,d) \) which multiplies two \( n \times n \) matrices of degree \( d \).

Proof. It follows from Lemma 4.1 with \( l = d \) that the first \( d+1 \) coefficients of \( a^*_j,i \) are given by

\[
a^*_{j,i,d-k} = \frac{\partial \Delta_d}{\partial a_{j,i,k}}, \quad 0 \leq k \leq d.
\]

By computing the partial derivatives \([12, 1]\) of the given program for the determinant coefficient \( \Delta_d \) we thus have a program of length bounded by \( 4D(n,d) \) for computing \( A^* \) mod \( x^{d+1} \). We conclude by applying this result twice to the well known \( 3n \times 3n \) matrix

\[
A = \begin{bmatrix}
I_n & A_1 \\
I_n & A_2 \\
I_n & \end{bmatrix}
\]

with \( A_1, A_2 \in K[x]^{n \times n} \) of degree \( d \).

The associated adjoint matrix is the matrix of degree \( 2d \)

\[
A^* = \begin{bmatrix}
I_n & -A_1 & A_1A_2 \\
I_n & -A_2 & \\
I_n & \end{bmatrix}
\]

One can thus recover \( A_1A_2 \mod x^{d+1} \) from \( A^* \mod x^{d+1} \). To get higher order terms, notice that if \( A_1A_2 = x^d H + L \) then \( H = A_1A_2 \mod x^{d+1} \) where \( M = \sum_{i=0}^{d} M_{d-i} x^i \) is the “mirror” polynomial matrix of \( M = \sum_{i=0}^{d} A_{d-i} x^i \). Therefore \( H \) and thus \( H \) can be recovered from \( A \mod x^{d+1} \). □

Following Giesbrecht [8, Theorem 1.3] we may state an analogous result for algorithms on an algebraic RAM: if we have a randomized Monte Carlo algorithm which computes \( \Delta_d \) with \( O(D(n,d)) \) operations in \( K \) then we have a Monte Carlo algorithm for multiplying two matrices of degree \( d \) with \( O(D(n,d)) \) operations in \( K \).

4.2 Polynomial matrix determinant

Over \( K \), algorithms for reducing determinant computation to matrix multiplication work recursively in \( O(\log n) \) steps. Roughly, step \( i \) involves \( n/2^i \) products of \( 2^i \times 2^i \) matrices. (See for example [17, 4].) When looking for the determinant of a polynomial matrix, both Storjohann’s algorithm [16] and the straight-line program we derive below from our previous studies in [21, 10] also work in \( O(\log n) \) steps. They involve polynomial matrices of dimensions \( 2^i \times 2^i \) and degree \( nd/2^i \) (this accounts for the definition of function \( \text{MM}'(n,d) \) in introduction).

In this section we study the costs of two different methods for computing the determinant of an \( n \times n \) polynomial matrix of degree \( d \). These costs are functions of \( \text{MM}'(n,d) \) and \( \text{MM}(n,d) \) and reduce both to \( O(n^d) \) when taking \( \text{MM}(n,d) = \Theta(n^d \log d \log \log d) \).

The first method is Storjohann’s high order lifting on an algebraic RAM [16]. We recall it briefly in §4.2.1 below for the sake of completeness. We then present in §4.2.2 an alternative approach for straight-line programs, which has been developed independently [21, 10].
4.2.1 Lifting determinant algorithms

Storjohann has given in [16, Proposition 24] a Las Vegas algorithm for computing the determinant of a polynomial matrix in $O(n^2d)$ operations. Without going into details since there is no change of the method, we point out that Storjohann’s result actually gives the following.

**Theorem 4.3** [16] The determinant of an $n \times n$ polynomial matrix of degree $d$ can be computed by a Las Vegas algorithm in $O(\text{MM}''(n,d) + \text{MM}(n,d)\log^2 n) + O(n^2d)$ or $O(n^2d)$ operations in $K$.

This complexity estimate may be deduced from the lines of [16]. The term in $O(\text{MM}''(n,d))$ comes from the integrality certificate and the Smith form computations of [16, Propositions 17 & 22]. The term in $O(\text{MM}(n,d)\log^2 n)$ comes from the high-order lifting of [16, Prop. 13] performed at each step of the $O(\log n)$ steps of the main iteration [16, §13].

4.2.2 Straight-line determinant

Given $A \in K[x]^{n \times n}$ of degree $d$ and sufficiently generic, the straight-line approach presented in [21, 10] computes the inverse of $A$ as $A^{-1} = B^{-1}U$ where $U \in K[x]^{n \times n}$ and $B \in K[x]^{n \times n}$ is diagonal of degree $nd$. One can further recover the determinant of $A$ from $B$ alone as we explain now. By definition of the inverse, $U = (\det A)^{-1}BA^*$ where $A^*$ is the adjoint matrix of $A$. Generically, deg det $A = \deg B = nd$ and $\det A$ is coprime with each entry $a_{i,j}^*$ of $A^*$. It follows that the diagonal entries $b_{i,i}$ of $B$ are nonzero constant multiples of $\det A$. Since $\det A(0)$ is generically nonzero, the determinant of a generic $A$ is thus equal to $(\det A(0))b_{1,1}/b_{1,1}(0)$ for $1 \leq i \leq n$.

To compute $B$ in Algorithm Determinant below, we proceed as for Algorithm Inverse in [10]: we diagonalize the input matrix in $\log n$ steps, starting with

$$A \rightarrow UA = \begin{bmatrix} U & A_L & A_R \end{bmatrix} = \begin{bmatrix} U & A_L & U \times A_R \end{bmatrix}$$

where $A_L, A_R \in K[x]^{n \times n/2}$ and where $U, L \in K[x]^{n/2 \times n}$ are minimal bases of the left kernels of $A_R, A_L$ respectively. These minimal bases are as in Theorem 3.5, for left kernels.

**Algorithm Determinant(A)**

**Input:** $A \in K[x]^{n \times n}$ of degree $d$.
**Output:** $\det A$.

**Condition:** $\det A(0) \neq 0$, $\gcd(a_{i,j}^*, \det A) = 1$, $\log n \in \mathbb{N}$.

$B := \text{copy}(A)$;
for $i$ from 1 to $\log n$ do

/* $B$ is block-diagonal with $2^{i-1}$ blocks $B_i^{(j)}$ */
for $j$ from 1 to $2^{i-1}$ do

$U^{(j)}_i := \text{a minimal basis of } \ker B_i^{(j),L}$;
$U^{(j)}_i := \text{a minimal basis of } \ker B_i^{(j),R}$;
od;
$U_i := \text{diag}(\begin{bmatrix} U^{(1)}_i \end{bmatrix}, \ldots, \begin{bmatrix} U^{(2^{i-1})}_i \end{bmatrix})$;
$B := U_iB$;
end;
return $(\det A(0))b_{1,1}/b_{1,1}(0)$;
The analysis of this algorithm is similar to the one of the inversion algorithm in [10] and we simply recall the key point for complexity: although the minimal bases in (11) can have degrees as large as \( nd \), they generically have degrees equal to \( d \) – a property which carries over the next step – and can then be recovered from the rows of any \( \sigma \)-bases of \( A_L, A_R \) with \( \sigma \geq n(2d+1) \) [10, Properties 1 & 2]. Generically, matrices \( B_{i,L}^{(j)} \) and \( B_{i,R}^{(j)} \) thus have dimensions \( 2^{1-i}n \times 2^{1-i}n \) and degree \( 2^{i-1}d \); it then follows from Theorem 2.4 that minimal kernel bases \( U_{i,L}^{(j)} \) and \( U_{i,R}^{(j)} \) can be computed in \( O(MM(2^{-i}n, 2^id)) \) operations in \( K \). On the other hand, the cost of matrix update \( B := U_iB \) is \( O(2^iMM(2^{p-i}, 2^id)) \) where \( MM(n, d) \leq MM(n, d) \). Hence the result below, recalling that the cost of computing \( \det A(0) \) is bounded by \( O(MM(n)) \).

**Theorem 4.4** The determinant of an \( n \times n \) polynomial matrix of degree \( d \) can be computed by a straight-line program over \( K \) of length \( O(\sum_{i=1}^{\log n} 2^iMM(2^{-i}n, 2^id)) \) or \( O(\tilde{n}^d) \).

## 5 Conclusion

In this paper we reduced polynomial matrix multiplication to determinant computation and conversely, under the straight-line model. Under the algebraic RAM model, we reduced the tasks of computing a \( \sigma \)-basis and column reduced form to the one of multiplying square polynomial matrices; as we have seen, similar reductions follow from [16] for the problems of computing the determinant and the Smith normal form.

However, in \( K[x]^{n \times n} \) it is still unclear whether
- Hermite and Frobenius normal forms,
- associated transformation matrices (even for the column reduced form),
- the characteristic polynomial,

can be computed in \( O(MM(n, d)) \) or \( O(\tilde{n}^d) \) operations in \( K \) as well. Another related question is to know whether the straight-line approach of section 4.2.2 yields a \( O(n^3d) \) algorithm for computing the inverse of a polynomial matrix.

## References

A Computed \textit{LSP} factorization

In Section 2 we assumed we use the \textit{LSP} algorithm of [9] as described in [3, p. 103]. In general, \textit{LSP} factorization is not unique: for example

\[
\begin{bmatrix}
0 & 0 \\
0 & 1 \\
\end{bmatrix} = \begin{bmatrix}
1 & * \\
1 & 0 \\
\end{bmatrix} \begin{bmatrix}
0 & 0 \\
1 & 1 \\
\end{bmatrix}.
\] (12)

However, with this choice of algorithm, some columns of \(L\) are prescribed as follows.

\textbf{Property A.1} \textit{If the \(i\)th row of} \(S\) \textit{is identically zero then the} \(i\)\textit{th column of} \(L\) \textit{is equal to the} \(i\)\textit{th unit vector}.

In (12) the computed factor \(L\) is thus the one with \(* = 0\).

\textit{Proof.} We use the notation of the solution to Problem 2.7c in [3, p. 103] and we assume without loss of generality that \(m\) is a power of two. The result is clear for \(m = 1\) since we take \(L = P = \begin{bmatrix} 1 \end{bmatrix}\). For \(m \geq 2\), assume that the result holds for \(m / 2\) and recall that in [3, p. 103] factors \(L, S\) are computed as

\[
L = \begin{bmatrix}
L_1 & G \\
L_2 & \end{bmatrix} \quad \text{and} \quad S = \begin{bmatrix}
S_1' & BP_2^{-1} \\
S_2 & \end{bmatrix}
\] (13)

where \(L_1, S_1 = [S_1', B]\) and \(L_2, S_2, P_2\) stem from \textit{LSP} factorizations of respective dimensions \(m / 2 \times m\) and \(m / 2 \times (m - r)\) where \(r \leq m / 2\) is the rank of \(S_1\). (We shall describe \(G\) later.) We consider two cases, depending on whether \(i > m / 2\) or \(i \leq m / 2\). If \(i > m / 2\) then the \((i - m / 2)\)th row of \(S_2\) is zero. By assumption, the \((i - m / 2)\)th column of \(L_2\) is therefore equal to the \((i - m / 2)\)th unit vector and the result follows from the shape of \(L\) in (13). If \(i \leq m / 2\) then the \(i\)th row of \(S_1\) is zero, for \(S_1 = [S_1', B]\) and \(P_2\) is a permutation matrix. Hence, by assumption, the \(i\)th column of \(L_1\) is the \(i\)th unit vector. To prove that the \(i\)th column of \(G\) is zero, recall first how \(G\) is defined in [3, p. 103]: \(G = FS_1^{(-1)}\) where \(F\) is a matrix of order \(m / 2\) whose last \(m / 2 - r\) columns are zero; additionally \(S_1^{(-1)}\) is a matrix of order \(m / 2\) that transforms \(S_1\) into

\[
S_1^{(-1)}S_1 = \begin{bmatrix}
I_r & * \\
O & O \\
\end{bmatrix} \in K_{m/2 \times m}.
\]

In particular \(S_1^{(-1)}\) contains a row permutation such that the \(i\)th row of \(S_1\) corresponds to a row of index greater than \(r\) in \(S_1^{(-1)}S_1\). The same permutation acts on the columns of \(F\) through transformation \(G = FS_1^{(-1)}\) and the \(i\)th column of \(G\) is therefore set to zero by definition of \(F\). \(\Box\)
