### Abstract

In this paper we compare three nested loops parallelization algorithms Allen and Kennedy-s algorithm Wolf and Lam-s algorithm and Darte and Vivien-s algorithm that use dierent representations of distance vectors as input. We identify the concepts that make them similar or different. We study the optimality of each with respect to the dependence analysis it uses. We propose well-chosen examples that illustrate the power and limitations of the three algorithms. This study permits to identify which algorithm is the most suitable for a given representation of dependences

# Introduction

Loop transformations have been shown to be useful for extracting parallelism from regular nested loops for a large class of machines, from vector machines and VLIW machines to multi-processors architectures. Of course, to each type of machine corresponds a different optimized code: depending on the memory hierarchy of the target, the granularity of the generated code must be carefully chosen so that memory accesses are optimized. Fine-grain parallelism is efficient for vector machines, whereas for shared-memory machines, coarse-grain parallelism (obtained by tiling or blocking techniques) is preferable and permits the reduction of inter-processor communications.

However, detecting parallelism (i.e. transforming  $\overline{DO}$  loops into  $\overline{DOALL}$  loops), and understanding parallelism (i.e. detecting which dependences are responsible for the sequentiality in the code) is independent of the target architecture. It only depends on the structure of the sequential code to be parallelized. This is certainly one of the reasons why a large amount of algorithms have been proposed for detecting **DOALL** loops, as a first step in the parallelization process. First, one studies the problem of parallelization on an ideal machine (a PRAM for example), and then, further optimizations are taken into account depending on the machine for which the code is to be com piled) such as the choice of granularity, the data distribution, the optimization of communications, ...This two-step approach is the most often used and not only in the field of automatic nested loops parallelization: this is also the case, among others, for general task scheduling or software pipelining

This paper studies different **parallelism detection algorithms** based on:

- i a simple decomposition of the dependence graph into its strongly connected components such as a algorithm Akademic and Kennedy-Akademic and Akademic and Akademic and Akademic and Akademic and Akademic
- ii unimodular loop transformations either adhoc transformations such as Banerjee-s algo rithm Ban or generated automatically such as Wolf and Lam-s algorithm WL
- iii schedules either monodimensional schedules KMW DKR Fea a a particular case being the hyperplane method Lam or multidimensional schedules DV Fea b

These algorithms seem very different not only by the techniques they use (graph algorithms for  $(i)$ , matrix computations for (ii), linear programming for (iii)), but also by the description of dependences they work with (graph description and level of dependences for  $(i)$ , direction vectors for  $(ii)$ , description of dependences by polyhedra for (iii)). Nevertheless, we try to identify the concepts that make these algorithms different or similar and we discuss their respective power and limitations.

Our main result is that all parallelizing algorithms that use information only on distance vectors, can be subsumed by a general algorithm, based on an algorithm first proposed by Karp, Miller and Winograd  $KMW67$  in the context of uniform recurrence equations. This algorithm has three main properties

- it can be adapted to all usual representations of distance vectors of distance vectors of distance vectors of
- it can be proven optimal with respect to the representation of dependences it works with
- it points out exactly which dependences are responsible for a loss of parallelism

Furthermore we show that Allen and Kennedy-s algorithm and Wolf and Lam-s algorithm are particular implementations of this algorithm for less accurate dependence representations As a consequence, they can also be proven optimal with respect to the dependence representation they use

This study permits to characterize exactly which algorithm is the most suitable for a given representation of dependences No need to use a sophisticated dependence analysis algorithm if the parallelization algorithm can not use the precision of its result Conversely no need to use a sophisticated parallelization algorithm if the dependence representation is not precise enough.

# Input and output of parallelization algorithms

Nested **DO** loops are one of the code structures that permit to describe a set of computations, whose size is not proportional to the code size. For example,  $n$  nested loops whose loop counters describe a n-cube of size *i*v, correspond to a set of computations of size *i*ve. Furthermore, it often happens that such loop nests contain a non trivial **degree of parallelism** (i.e. sets of independent computations of size  $\Omega(N^r)$  for  $r \geq 1$ ).

This aspect makes the parallelization of nested loops a very challenging problem a compiler parallelizer must be able to detect if possible a non trivial degree of parallelism with a compilation time not proportional to the sequential execution time of the loops. To make this possible, efficient parallelization algorithms must be proposed with a *complexity*, an *input size* and an *output size* that depend only on n but certainly not on  $N$ , i.e. that only depend on the size of the sequential code and not on the number of computations it describes The input of parallelization algorithms is a description of the dependences that link the different computations generated by the loop nest, the output is a description of an equivalent code with explicit parallelism

#### $2.1$ Input: reduced dependence graph

Each iteration of the loops that surround a statement corresponds to a particular execution of the statement, that we call an **operation**. The dependences between operations are represented by a directed acyclic graph that has as many vertices as operations: the **expanded dependence graph** (EDG). Executing the operations of the loop nest while respecting the partial order specified by the EDG guarantees that the result of the loop nest is preserved. Detecting parallelism in the loop nest means detecting anti-chains in the EDG.

Unfortunately, in general, the EDG can not be used as an input for parallelization algorithms, since it is too large (it has as many vertices as operations described by the loop nest) and may not be described exactly at compile-time. One prefers to manipulate the **reduced dependence graph**  $(RDG)$  which is a representation, in a condensed form, of an approximate EDG. This approximation must be a superset of the EDG so that dependence relations are preserved. The RDG has as one vertex per statement in the loop nest and its edges are labelled in a way depending on the chosen approximation we will recall how in section we will recall how in section will be a survey on dependence tests as gcd test, power test, omega test, lambda test, and [Fea91] for more details on exact dependence analysis

Since its input is the RDG and not the EDG, a parallelization algorithm is not able to distinguish between two different EDGs which have the same RDG. The parallelism that can be detected is then the parallelism contained in the RDG. Thus, the quality of a parallelization algorithm must be studied *with respect to* the dependence analysis.

# 2.2 Output: nested loops

The size of the parallelized code, as noticed before, should not depend on the number of operations it describes This is the reason why the output of a parallelization algorithm must always be described by a set of loops

For the sake of clarity, we restrict ourselves to the case of perfectly nested DO loops with affine loop bounds, even if the algorithms presented in the next sections can be extended to more complicated nested loops. This permits to identify, as usual, the iterations of n nested loops  $(n \text{ is } n)$ called the  $\alpha$ epth of the loop nest) with vectors in  $\mathbb{Z}^n$  (called the **iteration vectors**) contained in a finite convex polyhedron bounded by the loop bounds (called the **iteration domain**). The *i*-th component of an iteration vector is the value of the *i*-th loop counter in the nest, counting from the outermost to the innermost loop. In the sequential code, the iterations are therefore executed in the lexicographic order of their iteration vectors

In the next sections, we will denote by P, the polyhedral iteration domain, by I and J,  $n$ dimensional iteration vector in P, and by  $S_i$ , the *i*-th statement in the loop nest. We will write  $I >_{l} J$  if I is lexicographically greater than J and  $I \geq_{l} J$  if  $I >_{l} J$  or  $I = J$ .

There are at least three ways to define a new order on the operations of a loop nest (i.e. three ways to define the output of the parallelization algorithm), that can be expressed by nested loops:

- to use elementary loop transformations as basic steps for the algorithm such as loop distri bution as in Allen and Kennedy-s algorithm or loop interchange and loop skewing as in Banerjee-s algorithm
- to apply a linear change of basis on the iteration domain ie to apply a unimodular trans formation on the iteration vectors as in Wolf and Lam-s algorithm
- to define a d-dimensional schedule, i.e. to apply an affine transformation from  $\mathbb{Z}^n$  to  $\mathbb{Z}^d$  and to interpret the transformation as a multi-dimensional timing function. Each component will correspond to a sequential loop, the missing  $(n - d)$  dimensions will correspond to **DOALL** loops as in Feautrier-s algorithm and Darte and Vivien-s algorithm

These three transformation schemes can be described by loop nests after more or less compli cated rewriting processes (see [WL91, DR94, Xue94, CFR94, Col94]). We will not discuss them here. We will rather study the link between the loops transformations involved (the output) and the dependences representation (the input), our goal being to characterize, for a given dependences representation, which algorithm is optimal, i.e. exhibits the maximal number of parallel loops.

# 2.3 Representations of dependences

In all dependence analysis methods, dependence relations between operations are defined by Bernstein-s conditions Ber Briey speaking two operations are considered dependent if both access the same memory location and if at least one access is a write. Furthermore, this dependence is directed according to the sequential order. Depending on the order of write(s) and/or read, this dependence corresponds to the so called **flow dependence**, anti dependence or output de**pendence**. We write:  $S_i(I) \Longrightarrow S_j(J)$  if statement  $S_j$  at iteration J depends on statement  $S_i$  at iteration I. The partial order defined by  $\implies$  describes the EDG <sup>2</sup>. Note that  $(J-I)$  is always lexicographically non negative when  $S_i(I) \Longrightarrow S_j(J)$ .

The RDG is a compression of the EDG. In the RDG, two statements  $S_i$  and  $S_j$  are said dependent (we write  $S_i \to S_j$ ) if there exists at least one pair  $(I,J)$  such that  $S_i(I) \implies S_i(J)$ .

 $1$ These loops can be arbitrary complicated, as long as their complexity only depends on the size of the initial code. Obviously the simpler the result the better But in this context the meaning of -simple is not clear it dependson the optimizations that may follow. We consider that structural simplicity is preferable, but this can be discussed.

In some cases output and anti dependences can be removed by data expansion See for example Fea

Furthermore, the dependence  $S_i \to S_j$  is labelled by the set  $\{(I,J) \in P^2 \mid S_i(I) \implies S_i(J)\}\,$  or by an approximation that contains this set The precision and representation of this approximation makes the power of the dependence analysis

For a certain class of nested loops it is possible to express exactly this set of pairs I-J (see [Fea91]): *I* is given as an affine function  $f_{i,j}$  of *J* where *J* varies in a polyhedron  $\mathcal{P}_{i,j}$ :<br>  $\{(I,J) \in P^2 \mid S_i(I) \Longrightarrow S_i(J)\} = \{(f_{i,j}(J), J) \mid J \in \mathcal{P}_{i,j} \subset P\}$  (1)

$$
\{(I,J) \in P^2 \mid S_i(I) \Longrightarrow S_j(J)\} = \{(f_{i,j}(J), J) \mid J \in \mathcal{P}_{i,j} \subset P\}
$$
\n(1)

In most dependence analysis algorithms however rather than the set of pairs I-J one com putes the set of values  $(J - I)$ . This latter is called the set of **distance vectors**, or **dependence** vectors. When exact dependence analysis is feasible, equation 1 shows that the set of distance vectors is the pro jection of the integer points of a polyhedron This set can be approximated by its convex hull or by a more or less accurate description of a larger polyhedron (or a finite union of polyhedra). When the set of distance vectors is represented by a finite union, the corresponding dependence edge in the RDG is decomposed into multi-edges.

We give below usual representations of the set of distance vectors (by decreasing precision).

- Rays and vertices A dependence analysis algorithm such as [IT87] provides a description of a dependence polyhedron by its vertices and rays - A dependence polyhedron with no vertices (or whose vertices have been converted to rays) is called a **dependence cone**. Very often the dependence polyhedron has a single vertex but many rays
- Direction vectors When the set of distance vectors is a singleton, the dependence is said uniform and the only distance vector is called a **uniform dependence vector**. Otherwise, the set of distance vectors can still be represented by a *n*-dimensional vector (called the **direction** and the only distance vector is called a **uniform dependence vector**. Otherwise, the set<br>of distance vectors can still be represented by a *n*-dimensional vector (called the **direction**<br>**vector**), whose components belong approximation of all possible *i*-th components of distance vectors: it is equal to  $z+$  (resp.  $z$ -) if all *i*-th components are greater than (resp. smaller than) or equal to z. It is equal to  $*$ if the *i*-th component takes any value and to z if the dependence is uniform in this dimension with unique value z. In general,  $+$  (resp.  $-$ ) is used as shorthand for  $1+$  (resp.  $(-1)$ ). Note that a direction vector can always be decomposed into several lexicographically non negative direction vectors. For example, the direction vector  $(0+,*)$  is decomposed into  $(+,*)$  and  $(0,0+)$  since the distance vectors  $(0,-)$  do not exist. In the rest of the paper, we will thus assume that all direction vectors are lexicographically non negative
- Level of dependence The coarsest representation of dependences is the representation by level. The set of distance vectors is represented by an integer p, in  $[1 \dots (n+1)]$ , defined as the largest integer such that the  $p-1$  first components of the distance vectors are zero. A dependence at level  $p \leq n$  means that the dependence occurs at depth p of the loop nest, i.e. at a given iteration of the  $p-1$  outermost loops. In this case, one says that the dependence is a **loop** carried dependence at level p or that the dependence is carried at level p. If  $p = n + 1$ , the dependence occurs inside the loop body, but between two different statements.

Note that the representation by distance vectors is not equivalent to the representation by pairs (as in equation 1), since the information concerning the **location** in the EDG of such a distance is lost. This may even be the cause of a loss of parallelism (see section  $3.3.3$ ). However, this representation remains important, especially when exact dependence analysis is either too expensive or not feasible

<sup>-</sup> In fact one could argue that the polyhedron is always bounded and thus has no rays However since loops arevery often parametrized some parametrized vertices are converted to non parametrized vertices and rays

#### 3 A study of different loops parallelization algorithms

In this section we present the main ideas of Allen and Kennedy-s algorithm Wolf and Lam-s algo rithm and Darte and Vivien-Calgorithm For each algorithm  $\alpha$  also an example that illustrates its power and an example that illustrates its limitations

#### 3.1 Allen and Kennedy's algorithm

Allen and Kennedy-s algorithm AK is based on the following facts

- i. An outermost loop is parallel if it has no loop carried dependence, i.e. if there is no dependence with level 1.
- ii. All iterations of a statement  $S_1$  can be carried out before any iteration of a statement  $S_2$  if there is no dependence in the RDG from  $S_2$  to  $S_1$ .

Property (i) permits to mark a loop as a  $\bf{DOALL}$  or a  $\bf{DOSEQ}$  loop, whereas property (ii) suggests that the parallelism detection can be done independently in each strongly connected component of the RDG The input of the algorithm is a description of the RDG whose edges are labelled by the levels of dependences. Parallelism extraction is done by loop distribution.

For a dependence graph G, we denote by  $G(k)$  the subgraph of G in which all dependences at level strictly smaller than  $k$  have been removed. Here is a sketch of the algorithm in its most basic formulation. The initial call is ALLEN-KENNEDY(RDG, 1).

# ALLEN-KENNEDY <sup>G</sup> <sup>k</sup>

- If kn stop
- Decompose Gk into its strongly connected components Gi and sort them topologically
- Rewrite code so that each Gi belongs to a dierent loop nest at level k and the order on the  $G_i$  be preserved (distribution of loops at level  $\geq k$ ).
- For each Gi mark the loop at level <sup>k</sup> as a DOALL loop if Gi has no edge at level k Otherwise mark the loop as a **DOSEQ** loop.
- $\mathcal{F}$  and  $\mathcal{F}$  called  $\mathcal{F}$  and  $\mathcal{F}$  and  $\mathcal{F}$  are alleged to the  $\mathcal{F}$  and  $\mathcal{F}$  are alleged to the  $\mathcal{F}$

### Example

```
DO i = 1, nDO i = 1, nDO k = 1, na(i, j, k) = a(i - 1, j + i, k) + a(i, j, k - 1) + b(i, j - 1, k)b(i, j, k) = b(i, j - 1, k + j) + a(i - 1, j, k)CONTINUE
```
The dependence graph  $G = G(1)$  drawn on figure 1 has only one strongly connected component and at least one edge at level thus the rst call has no eect However at level the edge at level is not considered G has two strongly connected components all computations on array <sup>b</sup> can be carried out before any computation on array a With a loop distribution at level and we get

Figure 1: Reduced Dependence Graph for Example 1 (with level of dependences)

```
DOSEQ 1 i = 1, nDOSEQ 
 j   n
       \sim \sim \sim \sim \sim \sim \sim \simb(i, j, k) = b(i, j - 1, k + j) + a(i - 1, j, k)\overline{2}CONTINUE
    DOALL 3 j = 1, nDOSEQ 3 k = 1, na(i, j, k) = a(i - 1, j + i, k) + a(i, j, k - 1) + b(i, j - 1, k)3 CONTINUE
1 CONTINUE
```
**Property 1** Algorithm  $ALLEN-KENNEDY$  is optimal among all parallelism detection algorithms whose input is a RDG labelled by the level of dependences.

**Proof:** The proof is based on the fact that algorithm ALLEN-KENNEDY has the same behaviour as data darte and Vivien-Dividence and Virginiar case of a RDG labelled by the level by the level of a RDG lab of dependences if all DOALL loops are made innermost The optimality of algorithm ALLEN KENNEDY is then a consequence of the optimality of Darte and Vivien-s algorithm in the general case precised by property 3.  $\Box$ 

Property 1 shows that algorithm ALLEN-KENNEDY is well adapted to a representation of dependences by level of dependences. Therefore, to detect more parallelism than found by algorithm ALLEN-KENNEDY, is possible only if more precision is given on the dependences. A classic example for which it is possible to overcome algorithm ALLEN-KENNEDY is an example where a simple interchange example or a simple skew and an interchange example 
 reveal parallelism see dependence graphs on gure

### Examples and

#### $3.2$ Wolf and Lam's algorithm

Examples and 
 contain parallelism However as shown by property this parallelism can not be extracted if the dependences are represented by level of dependences only To remedy this

Figure  Reduced Dependence Graphs for Examples and

limitation, Wolf and Lam [WL91] proposed an algorithm that uses direction vectors as input. Their work unified all previous algorithms based on elementary matrix operations such as loop skewing. loop interchange, loop reversal, in a unique framework, the framework of **valid unimodular** transformations

Looking for unimodular transformations is of practical interest since they are linear invertible in  $\mathbb Z^+$ . Given a unimodular transformation  $I$  , property (1) permits to check if  $I$  is valid  $\sum_{i=1}^{n}$  is valid if  $\sum_{i=1}^{n}$  of lot all non-zero distance vectors  $\alpha$  and property  $\sum_{i=1}^{n}$  permitted to rewrite the code (simple change of basis in  $\mathbb{Z}^n$ ). In general, since T  $a >_l 0$  can not be checked for an *alstance*  $\alpha$  , occord, one tries to guarantee  $\pm a$  is for all non zero all cotton vectors, with the usual arithmetic the code (simple change of basis in<br>vectors, one tries to guarantee  $Td$ <br>conventions in  $\mathbb{Z} \cup \{*\} \cup (\mathbb{Z} \times \{+, -\}$  $-\})$ . In the following, we consider only non zero direction vectors that we can thus assume leaves as summer less assume less assume less assume less assume  $\mathbf{r}$ 

Denote by t tn the rows of <sup>T</sup> For a direction vector <sup>d</sup>  $\tau$   $t(1), \ldots, t(n)$ , the rows of  $T$ . For<br>  $Td >_l 0 \Leftrightarrow \exists k_d, 1 \leq k_d \leq n \mid \forall i, 1$ 

$$
Td >_{l} 0 \Leftrightarrow \exists k_d, \ 1 \leq k_d \leq n \mid \forall i, \ 1 \leq i < k_d, \ t(i).d = 0 \text{ and } t(k_d).d > 0.
$$

This means that the dependences represented by d are carried at loop level  $k_d$ . If  $k_d = 1$  for all direction vectors  $d$ , then all dependences are carried by the first loop, and all inner loops are **DOALL** loops.  $t(1)$  is then called a **timing vector** or **separating hyperplane**. Such a timing vector exists if and only if  $\Gamma$ , the closure of the cone generated by all direction vectors, is pointed. **DOALL** loops.  $t(1)$  is then called a **timing vector** or **separating hyperplane**. Such a timing vector exists if and only if  $\Gamma$ , the closure of the cone generated by all direction vectors, is pointed.<br>This is also equi is full-dimensional (see [Sch 86] for more details on cones and related notions). Building T from  $n$ imearly independent vectors of  $1^+$  permits to transform the loops into  $n$  fully permutable loops.

The notion of timing vector is in the heart of the hyperplane method and its variants (see [Lam74,  $DKR91$ , which are particularly interesting for exposing fine-grain parallelism, whereas the notion of fully permutable loops is the base of all tiling techniques [IT88, SD90, BDRR94, WL91], which are used for exposing coarse-grain parallelism. As said before, both formulations are equivalent when reasoning on

When the cone  $\Gamma$  is not pointed,  $\Gamma^+$  has a dimension r,  $1 \leq r \leq n$ ,  $r = n - s$  where s is the dimension of the lineality space of  $\bf{l}$  . With  $\bf{r}$  inearly independent vectors of  $\bf{l}$  , one can transform the loop nest so that the r outermost loops are fully permutable. Then, one can recursively apply the same technique for transforming the  $n-r$  innermost loops, by considering the direction vectors not already carried by at least one of the  $r$  outermost loops (i.e that belong to the lineality space of all the state general idea of Wolf and Lamp- in the state is not explicitly described in these terms in [WL91]. This can be summarized by algorithm WOLF-LAM given below. Algorithm WOLF-LAM takes as input a set of direction vectors  $D$  and a sequence of linearly independent vectors  $E$  (initialized to void) from which the transformation matrix is built:

# $\ldots$   $\ldots$   $\ldots$   $\ldots$   $\ldots$   $\ldots$   $\ldots$   $\ldots$

- Dene as the closure of the cone generated by the direction vectors of D Define  $\Gamma$  as the closure of the cone generated by the direction vectors of<br>Define  $\Gamma^+ = \{y \mid \forall x \in \Gamma, y.x \ge 0\}$  and let r be the dimension of  $\Gamma^+$ .
- 
- Complete E into a set E' of r linearly independent vectors of  $\Gamma^+$  (by construction,  $E \subset \Gamma^+$ ).
- Complete E into a set E' of r linearly independent vectors of  $\Gamma^+$  (by construction,  $E \subset \Gamma^+$ ).<br>Let D' be the subset of D defined by  $d \in D' \Leftrightarrow \forall v \in E'$ ,  $v.d = 0$  (i.e.  $D' = D \cap E'^{\perp} =$  $D \cap \text{linspace}(\Gamma)$ .
- Call WOLF-LAM $(D', E')$ .

Now, building the desired unimodular matrix  $T$  can be done as follows:

- Let D be the set of direction vectors. Set  $E = \emptyset$  and call WOLF-LAM $(D, E)$ .
- Build a non singular matrix T whose rst rows are the vectors of <sup>E</sup> in the same order Let  $T_2 = pT_1$  where p is chosen so that  $T_2$  is an integral matrix.
- Compute the left Hermite form of T T QH where <sup>H</sup> is non negative lower triangular and Q is unimodular.
- $Q^{-1}$  is the desired transformation matrix (since  $pQ^{-1}D = HT_1D$ ).

 $R$ emark This algorithm is not exactly the original Wolf and Lam- $\mu$ principle is similar. Wolf and Lam build the matrix  $T$ , step by step, during the algorithm, as a product of unimodular matrices Furthermore they do not compute exactly but they propose heuristics and special algorithms for some particular cases.

### Example

```
DO i = 1, nDO j = 1, nDO k = 1, na(i, j, k) = a(i - 1, j + i, k) + a(i, j, k - 1) + a(i, j - 1, k + 1)CONTINUE
```

Figure 3: Reduced Dependence Graph for Example 4 (with direction vectors)

The set of direction vectors is  $D = \{(1, -0), (0, 0, 1), (0, 1, -1)\}$  (see figure 3). The lineality space of  $1$  (D) is two-dimensional (generated by  $(0,1,0)$  and  $(0,0,1)$ ). Thus,  $1^+(D)$  is one dimensional and generated by  $E_1 = \{(1,0,0)\}\.$  Then  $D' = \{(0,0,1), (0,1,-1)\}\$  and  $\Gamma(D')$  is pointed. We complete  $E_1$  by two vectors of  $\Gamma^+(D')$ , for example by  $E_2 = \{(0,1,0), (0,1,1)\}\.$  In this particular example, the transformation matrix whose rows are E- $_1$  p  $_2$  is already unimodular and corresponds to a simple loop skewing. For exposing **DOALL** loops, we choose the first vector of  $E_2$  in the relative interior of  $\Gamma^+$ , for example  $E_2 = \{(0,2,1), (0,1,0)\}\.$  This corresponds in terms of loops transformations to skew the loop <sup>k</sup> by factor and then to interchange loops <sup>j</sup> and <sup>k</sup>

DOSEQ 
$$
i = 1, n
$$
  
\nDOSEQ  $k = 3, 3 * n$

Wolf and Lam showed that this methodology is optimal (Theorem B.6. in [WL91]): "an algorithm that finds the maximum coarse grain parallelism, and then recursively calls itself on the inner loops, produces the maximum degree of parallelism possible". Strangely, they gave no hypothesis for such a theorem. However, once again, this theorem has to be understood with respect to the dependence analysis that is used: here, direction vectors but with no information on the structure of the dependence graph. A correct formulation is the following:

**Property 2** Algorithm WOLF-LAM is optimal among all parallelism detection algorithms whose input is a set of direction vectors -implicitely one thus considers that the loop nest has only one statement or that all statements form an atomic block).

Proof Once again we use the optimality of Darte and Vivien-s algorithm on a loop nest whose body has only one statement, and whose dependences are represented by direction vectors, Darte and virien-s algorithm has the same as algorithm working the same of  $\sim$  and  $\sim$ 

Therefore, as for algorithm ALLEN-KENNEDY, the sub-optimality of algorithm WOLF-LAM in the general case has to be found, not in the algorithm methodology, but in the weakness of its input the fact that the structure of the RDG in terms of strongly connected components is not exploited results in a loss of parallelism. For example, algorithm WOLF-LAM finds no parallelism in example 1 (whose RDG is given by figure 4) because of the typical structure of the direction vectors  $(1, -, 0), (0, 1, -), (0, 0, 1).$ 

Figure 4: Reduced Dependence Graph for Example 1 (with direction vectors)

# 3.3 Darte and Vivien's algorithm

One can imagine to combine algorithms WOLF-LAM and ALLEN-KENNEDY, so as to exploit simultaneously the structure of the RDG and the structure of the direction vectors: first, compute the cone generated by the direction vectors and transform the loop nest to expose the largest outermost fully permutable loop nest; then, consider the subgraph of the RDG, formed by the direction vectors that are not carried by the outermost loops and compute its strongly connected components; finally, apply a loop distribution in order to separate these components and apply the same technique, recursively on each component.

Such a strategy permits to expose more parallelism by combining unimodular transformations and loop distribution. However, it is not optimal as example 5 illustrates. We will indeed see that the key concept is not the cone generated by the direction vectors (i.e. the weights of the edges of the RDG), but the cone generated by the *weights of the cycles* of the RDG. This remark leads to the multi-dimensional scheduling algorithm of Darte and Vivien [DV94] that can be seen as a combination of unimodular tranformations, loop distribution, and index-shift method.

### Example

```
DO i = 1, nDO j = 1, nDO k = 1, nai ji k bi bi bi bi ji kati bi ji bi j
         b(i, j, k) = a(i, j - 1, k + j) + a(i, j, k - 1)CONTINUE
```

Figure 5: Reduced Dependence Graph for Example 5 (with direction vectors)

On this example (whose RDG is given on figure  $5$ ), combining algorithms ALLEN-KENNEDY and WOLF-LAM, as proposed above, finds only one degree of parallelism (since at the second phase the RDG remains strongly connected). This is not better than the basic algorithm ALLEN-KENNEDY. However, one can find two degrees of parallelism in example 5 (see below).

s reconstruction and and virtuous motivation was to not an algorithment.

- that is exible enough to support all representations of distance vectors based on a polyhedral representation
- that detects the maximal degree of parallelism contained in the RDG

## Canonical representation of the RDG

The first point is that any RDG, whose edges are labelled by a polyhedral representation of the distance vectors, can be simulated by a RDG, whose edges are labelled by dependence vectors.

Consider the particular case of a dependence between two statements  $S_1$  and  $S_2$  whose associated distance vectors are represented by a polyhedron with a single vertex  $w$  and a single ray  $r$ . This means that, in the RDG, one considers that all distance vectors of the form  $w + \lambda r$  (with  $\lambda \ge 0$ ) exist, and that, in the EDG, there is a dependence path of length 1, from  $S_1(I)$  to  $S_2(I + w + \lambda r)$ , for all  $\lambda \geq 0$  and for all I in P (the iteration domain) such that  $(I + w + \lambda r)$  belongs to P.

Thus, the situation is the same as if there were a *virtual* statement V, with a uniform selfdependence r, and two uniform dependences, w from  $S_1$  to V and 0 from V to  $S_2$ . For simulating the distance vector  $w + \lambda r$ , use once the edge from  $S_1$  to V, then turn  $\lambda$  times around V, and finally go to S However this simulation corresponds to a dependence path of length instead of To suppress this difference, one assigns a **delay** to each edge, 1 to the edge labelled by w and 0 to the others The length of a simulated path is then the sum of the delays along the edges it uses

This simulation is the base of Darte and Vivien-s algorithm whose rst phase consists in trans forming a RDG, whose edges are labelled by polyhedra, into an equivalent RDG, whose edges are labelled by weights (dependence vectors) and delays  $(0 \text{ or } 1)$ , and whose vertices form two classes: the actual vertices and the virtual vertices. This phase is done by the algorithm TRANSFORM:

## TRANSFORM COMPUTER COMPU

- 
- $\mathbf{r}$  and edges e  $\mathbf{w}$  (weight) or  $\mathbf{v}$  (decay a virtual vertex  $\mathbf{v}$  is
- If e is incomentally a polyhedron with vertices  $\sigma_1, \ldots, \sigma_l, \sigma_{l+1}, \ldots, \sigma_{l}$  and incoment  $\sigma_{l+1}, \ldots, \sigma_{k}$ 
	- $-$  suppress the edge  $e$ .
	- $\alpha$  create i eagles from  $x_{e}$  to  $\alpha$  is inserious by v<sub>1</sub>,  $\alpha$ <sub>1</sub>,  $\alpha$ <sub></sub>
	- create j self-loops around ve labelled by r-printing with a delay of
	- create 2k self-loops around  $V_e$  labelled by  $l_1, \ldots, l_k$  and  $-l_1, \ldots, -l_k$ , with a delay 0.
	- create one edge from  $V_e$  to  $y_e$  labelled by the null vector 0, with a delay 0.
- Return the transformed graph.

**Remark:** when the polyhedron that labels an edge  $e$  has neither rays, nor lines, it is not necessary to create a virtual vertex. One can create edges directly from  $x_e$  to  $y_e$ .

For example, a representation of dependences by level correspond to a particular representation by direction vectors: a dependence at level  $p \leq n$  is equivalent to the direction vector  $\cdot$   $\cdot$ p- $\overline{\phantom{a}}$  - $\overbrace{0,\ldots,0}^{0,1,\ast,\ldots,\ast}$ . A representation by direction vectors is equivalent to a representation with  $n-p$ 

uniform dependences and virtual vertices. For example, the direction vector  $(0, 1, 0-)$  corresponds to a polyhedron with one vertex  $(0,1,0)$  and one ray  $(0,0,-1)$ , whereas the polyhedron that corresponds to  $(1, 2+, *)$  has one vertex  $(1, 2, 0)$ , one ray  $(0, 1, 0)$  and one line  $(0, 0, 1)$ .

## Scheduling a system of uniform recurrence equations

Note that a RDG built by the algorithm TRANSFORM does not always correspond to the RDG of a loop nest since dependence vectors are not anymore lexicographically non negative. In fact, (if one forgets that some vertices are virtual and that some edges have delay  $0$ , this is the RDG of a system of uniform recurrence equations  $(SURE)$ , introduced, in a seminal paper, by Karp, Miller and Winograd [KMW67].

Karp, Miller and Winograd studied the problem of computability of a SURE: they showed that it is linked to the problem of detecting cycles of null weight in the reduced dependence graph  $G$ , and that it can be solved by a recursive decomposition of the graph, based on the detection of multi-cycles (i.e. union of cycles) of null weight. The key structure of their algorithm is  $G'$ , the subgraph of G generated by the edges that belong to a multi-cycle of null weight.

Darte and Vivien showed that  $G'$  can be efficiently built by the resolution of a simple linear program program or its dual program 
 This resolution permits to design a parallelization algorithm whose principle is dual to Karly Miller and Winograd-Winograd-Winograd-

$$
\min\left\{\sum_{e} v_{e} \mid q \ge 0, v \ge 0, w \ge 0, q+v=1+w, Bq=0\right\}
$$
 (2)

$$
\max\left\{\sum_{e} z_e \mid z \geq 0, \ 0 \leq z_e \leq 1, \ Xw(e) + \rho_{y_e} - \rho_{x_e} \geq z_e \right\} \tag{3}
$$

Without entering the details, X is a *n*-dimensional vector and there is one variable  $\rho$  per vertex of the RDG and one variable z per edge of the RDG. The edges of G' (resp.  $G \setminus G'$ ) are the edges  $\epsilon$  (weight for which  $\lambda_{\rm g}$  and  $\lambda_{\rm g}$  in the optimal solution of the dual (program b), and equivalently for which ve resp ve in the primal program When summing inequations  $Xw(e) + \rho_{y_e} - \rho_{x_e} \geq z_e$  on a cycle C of G, one finds that  $Xw(C) = 0$  if C is a cycle of G' and  $Xw(C) \ge l(C) > 0$  otherwise  $(l(C))$  is the length of the cycle C.

In other words and to see the link with algorithm WOLF-LAM, when considering the cone  $\Gamma$ generated by the weights of the cycles (and not the weights of the edges),  $G'$  is the subgraph whose cycle weights generate the lineality space lin space  $(\Gamma)$  of  $\Gamma$  and X is a vector of the relative interior of F  $\,$  . However, there is no need to build I effectively for building  $\,$  . This is one of the interest  $\,$ of linear programs and programs in the contract of the contrac

these are the modication is the main ideas of Darte and Viriense technical modications are technical modicatio that are needed to distinguish between virtual and actual vertices, to take into account the delay of the edges and the nature of the edges (vertices, rays or lines of a dependence polyhedron). The general principle of Darte and Virien-Virien-Virien-Virien-Virien-Virien-Virien-Virien-Virien-Virien-Virien-Vi

- Apply a global loop distribution for separating the dierent strongly connected components  $G_i$  of the RDG  $G$ .
- For each component Gi that has at least one edge compute its transformed graph Hi TRANSFORM $(G_i)$  and call DARTE-VIVIEN $(H_i, 1)$ .

Algorithm DARTE-VIVIEN is given below. It takes as input a transformed RDG, strongly connected, with at least one edge, and it returns a so called multi-dimensional schedule, i.e, for each actual vertex  $v,$  a set of  $a_v$   $n$ -dimensional vectors  $\bm{\Lambda}_1, \ldots, \bm{\Lambda}_{d_v}$  and  $a_v$  constants  $\rho_1, \ldots, \rho_{d_v},$  such that computing the iteration T of the statement  $S_v$  at the multi-dimensional step  $(X_1^1 \mathcal{A} + \rho_1^1, \dots, X_{d_v}^1 \mathcal{A} +$  $\rho_{d_{v}}$ ) leads to a valid schedule (if these steps are lexicographically ordered).

# ————————————————————

- $\bullet$  Build G', the subgraph of G generated by the edges that belong to a multi-cycle of null weight.
- For a given dependence polyhedron, add in  $G'$  all the edges that simulate this polyhedron, if at least one of the edges that correspond to its vertices is already in  $G'$  (technical modification).
- $\mathcal{F}$  and a vector  $\mathcal{F}$  and constants v such that  $\mathcal{F}$

$$
\begin{cases} Xw(e) + \rho_{y_e} - \rho_{x_e} \ge 0 \text{ for all edges } e = (x_e, y_e) \in G' \\ Xw(e) + \rho_{y_e} - \rho_{x_e} \ge d_e \text{ for all edges } e = (x_e, y_e) \notin G' \text{ with delay } d_e \end{cases}
$$

For all actual vertices v of G, let  $\rho_k^v = \rho_v$  and  $X_k^v = X$ .

• If  $G'$  is empty, return.

 $\overline{a}$ 

- If G' is strongly connected and has at least one actual vertex, G is not computable (and the initial RDG is not consistent
- Otherwise, decompose G' into its strongly connected components  $G_i$  and for each  $G_i$  that has at least one actual vertex, call DARTE-VIVIEN $(G_i, k+1)$ .

Figure 6: Transformed Reduced Dependence Graph for Example 5

We now go back to example 5. The transformed RDG is given on figure 6. It has 4 vertices (two of them are virtual). The weights of elementary cycles are  $(0,0,-1)$  and  $(0,-1,0)$  for the self-loops and  $(1,0,-1)$ ,  $(1,-1,1)$ ,  $(0,2,-3)$ ,  $(0,1,-1)$  for the other elementary cycles. Therefore,  $\Gamma$  is pointed and one can find a one-dimensional schedule, for example given by  $X = (4, 0, -2)$ ,  $\rho_a = 0$  and  $\rho_b = 3$ . Two degrees of parallelism can be exposed and the resulting code is then:

```
DOALL i = \max(1, |\frac{n+1}{2}|), \min(n, |\frac{n+1}{2}|)DOALL 1 j = 1, nai ji kale wa shekara wa shekara
 CONTINUE
   DOSEQ 
 k    n 
  n  
      DOALL 3 i = \max(1, |\frac{n+1}{2}|), \min(n, |\frac{n+1}{2}|)DOALL 3 j = 1, nai ji kale wa shekara w
 CONTINUE
      DOALL 4 i = \max(1, |\frac{\pi}{2}|), \min(n, |\frac{\pi}{2}|)DOALL 4 j = 1, n\mathbb{P}\left( \mathcal{X} \right) , and a subset of \mathcal{X} is a subset of \mathcal{X} , and \mathcal{X} is a subset of \mathcal{X} CONTINUE
```

```
DOALL \vartheta i = \max(1, |\frac{\pi}{2}|), \min(n, |\frac{\pi}{2}|)DOALL 5 j = 1, n\mathbb{P}\left( \left\{ \left\vert \left\vert \left\vert \left\vert \left\vert \left\vert \left\vert \right\vert \right\vert \right\vert \right\vert \right\vert \right\vert \right\} \right)5 CONTINUE
```
**Property 3** Algorithm DARTE-VIVIEN is optimal among all parallelism detection algorithms whose input is a graph whose edges are labelled by a polyhedral representation of distance vectors.

**Proof:** Consider a loop nest whose reduced dependence graph is G. Let  $H = \text{TRANSFORM}(G)$ and  $d = \max\{d_v \mid v \text{ actual vertex of } H\}$  where  $d_v$  has been given by algorithm DARTE-VIVIEN for each actual vertex of H, thus for each vertex of G. d is the recursion depth of algorithm DARTE-VIVIEN. The transformed code contains at most d nested sequential loops  $((n - d)$  degrees of parallelism are exposed). Furthermore, for a loop nest whose iteration domain contains (resp. is contained in) a *n*-dimensional cube of size N (resp.  $\lambda N$  for some  $\lambda \geq 1$ ), one can build a dependence path of length  $\Omega(N^d)$  in the EDG that corresponds to G (this is the difficult part of the proof). Therefore, any parallelization algorithm would expose a sequentiality of  $\Omega(N^d)$ . Since the sequentiality exposed by algorithm DARTE-VIVIEN is  $O(N^d)$ , it is optimal.

Studying the transformed RDG of examples 1 to 4 permits to better understand why parallelism were (or were not) found by the previous algorithms. The dependences that are responsible for the inherent sequentiality of the loop nest are exactly those that correspond to edges of  $G'$ . This has two consequences

- If G' has only flow dependences, there is no need to transform the code into single assignment form since this would not increase the degree of parallelism in the code
- If the dependence analysis is not exact,  $G'$  shows which edges deserve a more accurate dependence analysis for detecting more parallelism. There is no need to give a more precise description of edges in  $G \setminus G'$  since they are not responsible for the loss of parallelism.

# 3.3.3 Limitations of Darte and Vivien's algorithm

Darte and Vivien-s algorithm is optimal for any polyhedral representation of distance vectors Prop erty 3). However, it may not be optimal if more information is given on the *pairs of iteration* vectors that induce a dependence. This comes from the fact that the set of distance vectors  $\{(J-I) \mid S_1(I) \Rightarrow S_2(J)\}\$ is the projection of the set  $\{(J-I, J) \mid S_1(I) \Rightarrow S_2(J)\}\$  (which is as precise as the set of pairs  $\{(I, J) | S_1(I) \Rightarrow S_2(J)\}\)$ . Therefore, the projection makes us believe that the distance vectors can take place anywhere in the iteration domain even if this is not true This loss of precision may be the cause of a loss of parallelism as example 6 illustrates.

# Example

```
DO i = 1, nDO i = i, na(i, j) = b(i - 1, j + i) + a(i, j - 1)b(i, j) = a(i - 1, j - i) + b(i, j - 1)CONTINUE
```

Figure 7: Reduced Dependence Graph for Example 6 (with direction vectors)

If the dependences are described by distance vectors, the RDG (see figure 7) has two selfarproximate it, with the two edges labelled by polyhedral both with the street and one rest in the spectively  $(0,1)$  and  $(0,-1)$ ). Therefore, there exists a multi-cycle of null weight. Furthermore, the two actual vertices belong to  $G$  . Thus, the depth of algorithm DARTE-VIVIEN is 2 and no parameterism can be found, from Four computing feature iver in the medical property inc second statement at step <sup>i</sup> <sup>j</sup> resp <sup>i</sup> j leads to a valid schedule that exposes one degree of parallelism

The technique used here consists in looking for multidimensional schedules whose linear parts (the vectors  $X$ ) may be different for different statements even if they belong to the same strongly connected component This is the base of Feautrier-s algorithm Fea b whose fundamental mathe matical tool is the affine form of Farkas lemma. Property 3 however, shows that there is no need to look for different linear parts (whose construction is more expensive and lead to more complicated rewriting processes) in a given strongly connected component of the current subgraph  $G'$ , as long as dependences are given by distances vectors. On the other hand, example 6 shows that it can be useful when a more accurate dependence analysis is available. Now, the only remaining open question concerns the optimality of Feautrier-s algorithm for which representation of the dependences is Feautrier-s algorithm optimal!

# Conclusion

\_\_

Our study offers a classification of loops parallelization algorithms. Our main results are the following Allen and Kennedy-s algorithm is optimal for a representation of dependences by level and Wolf and Lam-s algorithm is optimal for a representation by direction vectors but for a loop nest with only one statement). Neither of them subsumes the other one, since each uses information that can not be exploited by the other (graph structure for the first one, direction vectors structure for the second one However both are subsumed by Darte and Vivien-s algorithm that is optimal for any polyhedral representation of distance vectors Feautrier-s algorithm is an extension of this latter, but the characterization of its optimality remains open.

We believe this classification of practical interest, since it permits a compiler-parallelizer to choose, depending on the dependence analysis at its disposal, the simplest and cheapest parallelization algorithm that remains optimal, i.e the algorithm that is the most appropriate to the available representation of dependences. Future work will try to answer the remaining open question concerning the optimality of  $\mathcal{L}$  algorithm of  $\mathcal{L}$  algorithm of  $\mathcal{L}$ 

\_\_

The schedules  $\lfloor \frac{1}{2}i + j + \frac{1}{2} \rfloor$  and  $\lfloor \frac{1}{2}i + j \rfloor$  minimize the latency but the code is more complicated to write.
